Thermography Study of the Client with Previously Diagnosed Cancer

Breast thermography is a non-contact, non-invasive procedure which captures and records temperature variations on the skin. The skin is the body's most intelligent organ and is "wired" with a communication network including all other organs and physiological processes in the body. The skin responds to physiological changes and a thermography device observes those changes. Assessments of these changes are reported by medical professionals trained to correlate thermal findings with a person's health history and concerns.

The highest use of thermal imaging is to thermally monitor dynamic changes in general health. This benefits the client with thermal images that includes multiple areas of the body. Be advised that initial imaging of only the breast provides limited information regarding the general health of the client.

Breast Thermography is not intended as a cancer detection test, as it does not suggest, confirm or rule out the possibility that cancer exists in the breast or any other area of the body.

Interpretation in your report does not include information or recommendations related to the measured changes of disease beyond skin temperature changes and patterns. As there is no single known test capable of monitoring all biological influences of the complex disease generally diagnosed as cancer, continued monitoring with available additional testing as recommended by your personal physician is strongly advised.

For preferred care, share the thermal findings and recommendations with a healthcare provider who is prepared to guide you in preserving your general health.
